

Machine Learning Approaches for Classification of Single Particle Aerosol Mass Spectra

Maria A. Zawadowicz, Brookhaven National Laboratory

with contributions from: José Perez-Chavez (Howard U) and Dan Cziczo (Purdue)

Aerosol chemistry measurements are an essential aerosol property

Aerosol composition is a frequently requested ARM capability.

The currently used technique, the ACSM only provides bulk non-refractory submicron aerosol composition

Why single particle?

CCN activation

Rierner, et al. (2019)

Heterogeneous ice nucleation

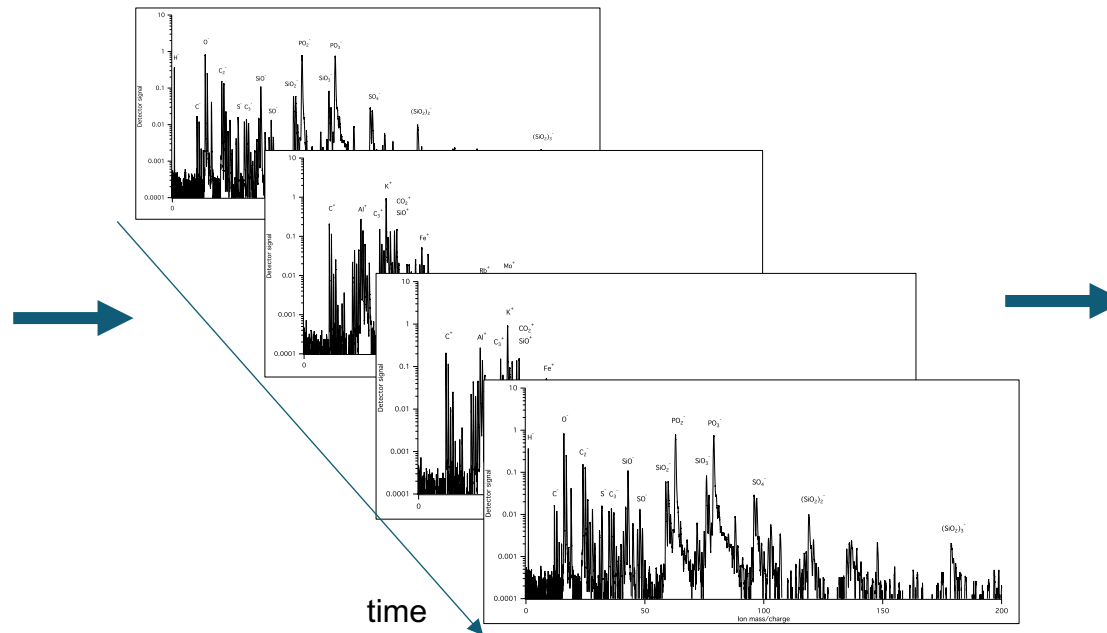

Many atmospheric processes, especially within the realm of aerosol-cloud interactions, depend strongly on properties of individual aerosol particles

"Bulk parametrizations" can result in model inaccuracies

For example, Zaveri, et al. (2010) found that averaging the CCN composition resulted in overestimates of 40% in CCN efficiency compared to a particle-resolving model.

Single-particle mass spectrometry at BNL

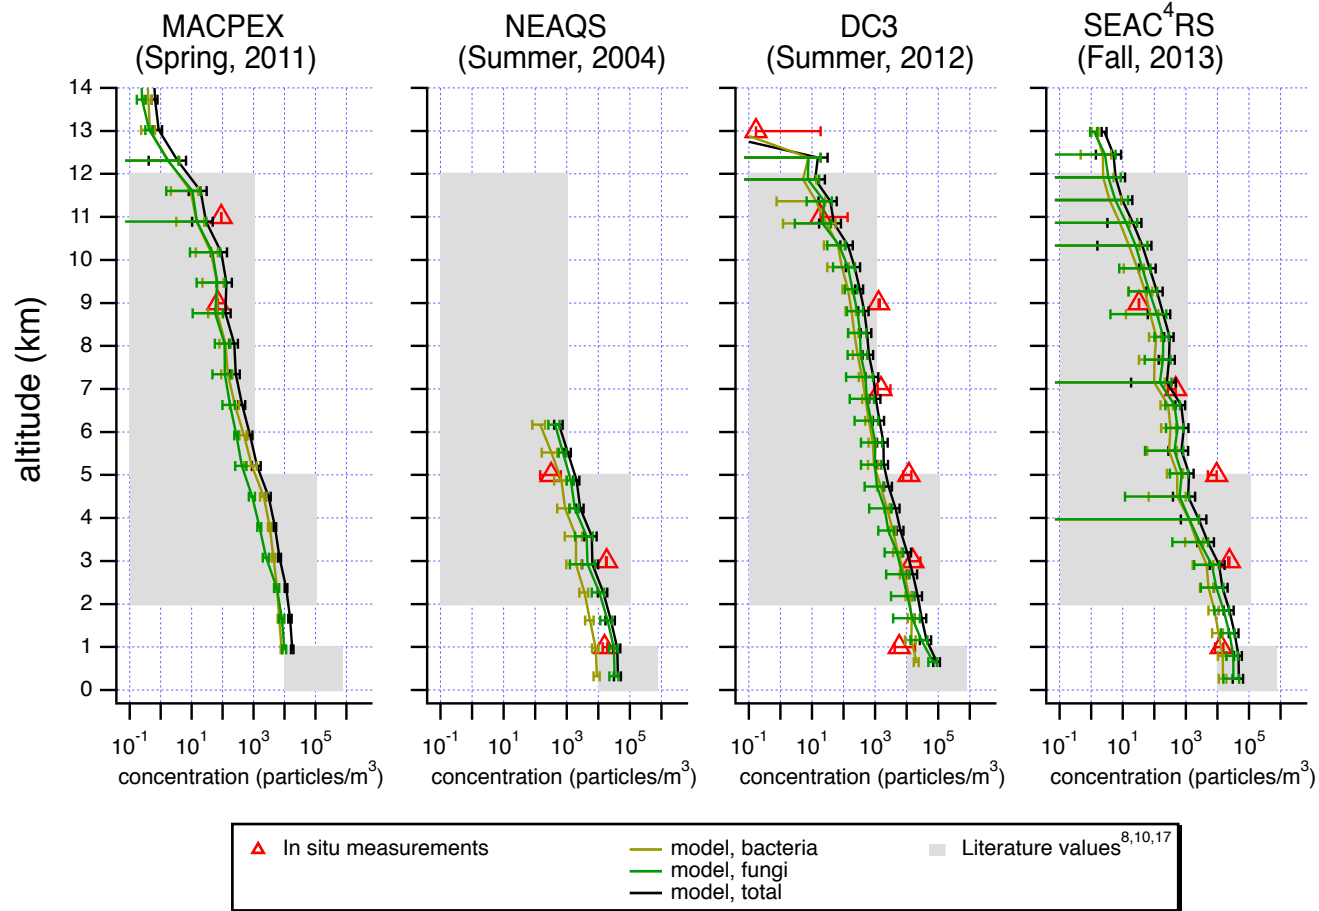

- Aims for the most comprehensive characterization of single particle composition to date through both hardware improvements and computational advances

Accuracy: 98.94%

Why mass spectrometry?

Because of its mode of ionization and single particle resolution, SPMS is sensitive to compositions that other aerosol measurements often miss, such as bioaerosol

Zawadowicz et al. (2019), ACP

Applications: ice and droplet residual composition

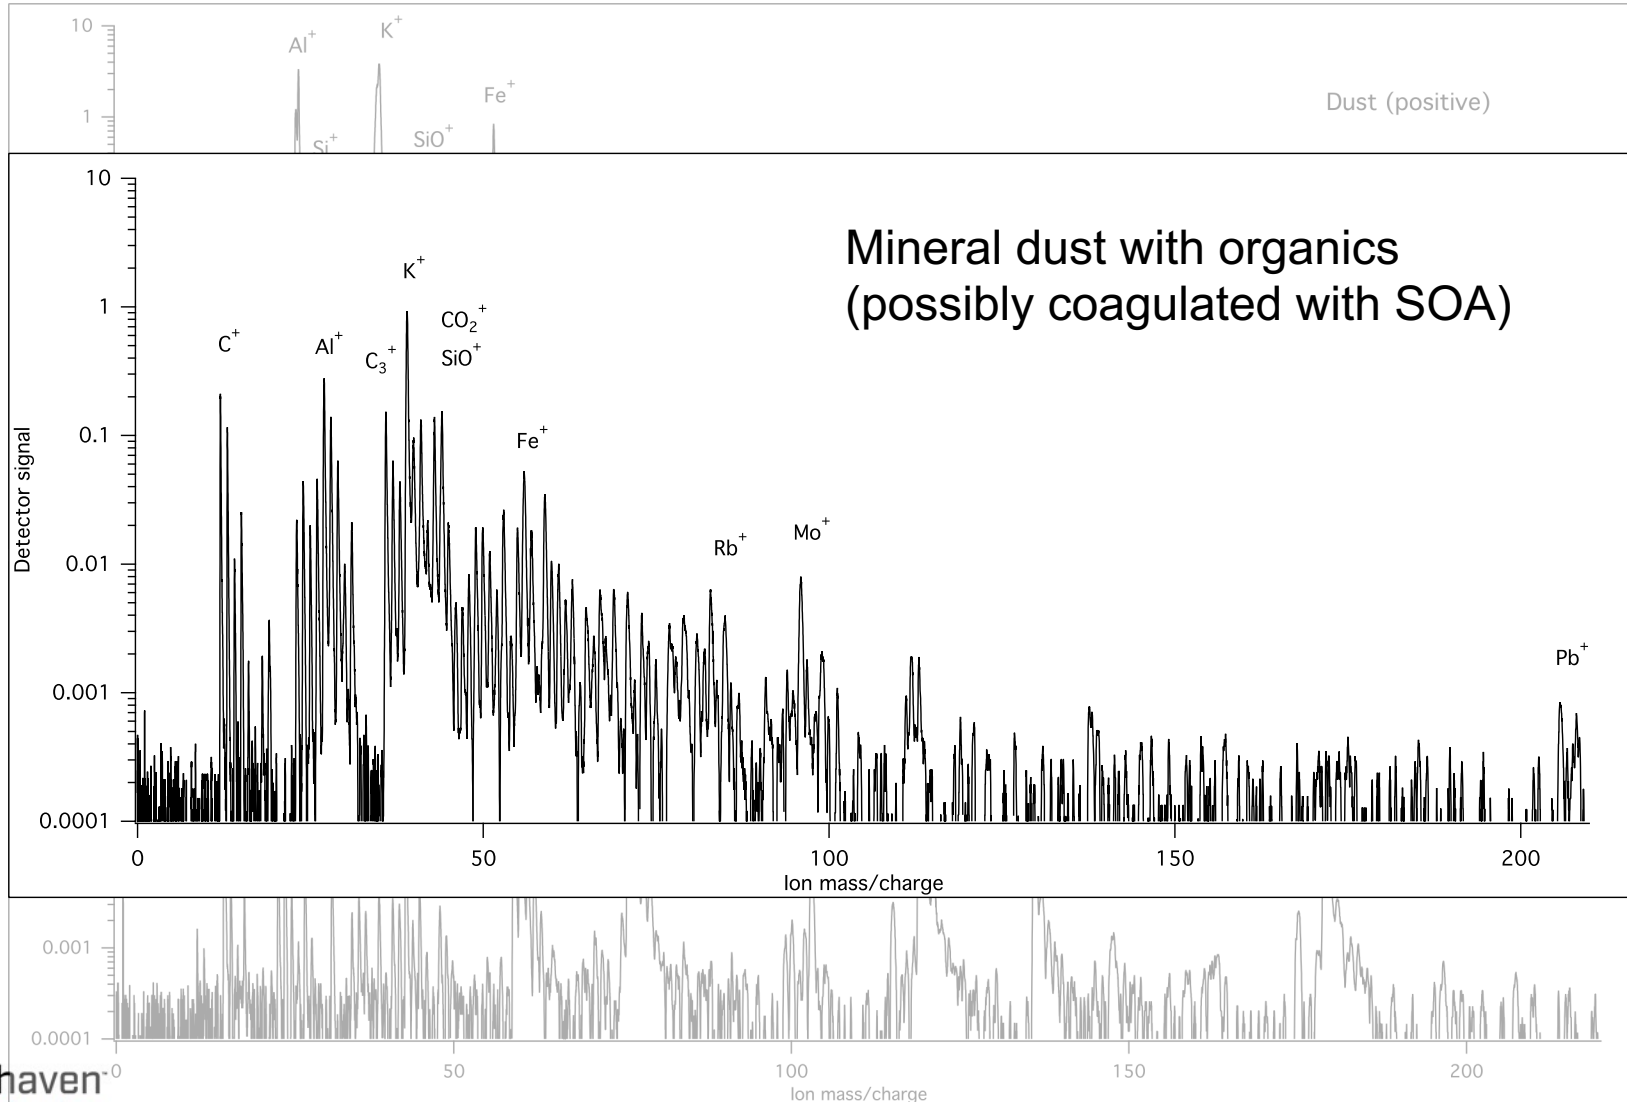

SPMS allows to probe the composition of single, evaporated ice crystals (ice residuals)

This study found a fingerprint associated with a secondary organic product of isoprene chemistry in ice residuals

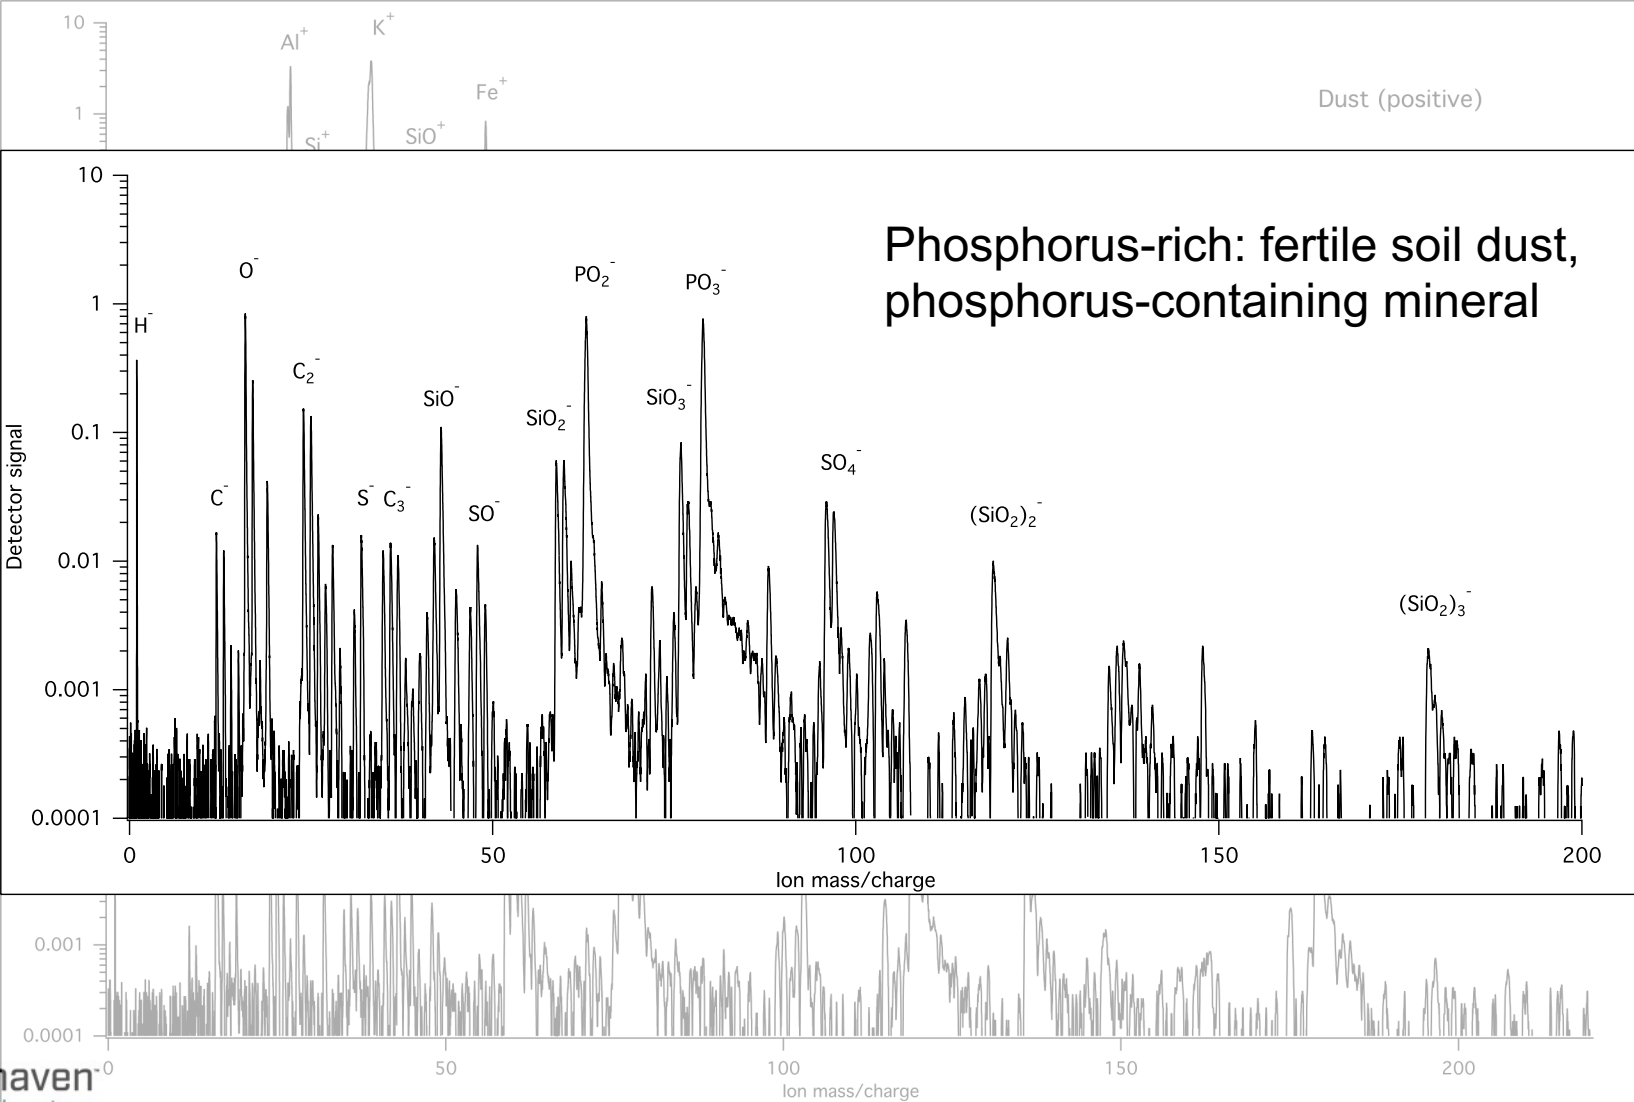

Single-particle mass spectra are challenging to interpret

Supervised classification approaches

Random forest supervised classifier produced encouraging results when tested on pure laboratory mass spectra but struggled when deployed on a "blind" mixture of aerosols.

Semi-supervised classification approaches

Strategy called “self-training” is used to train a stacked autoencoder neural network:

- (1) labeled dataset is used to train the classifier.
- (2) the trained classifier is used on the unlabeled dataset to classify it.
- (3) spectra with the highest classification certainty are selected and reviewed for any errors.
- (4) correctly classified spectra are then incorporated into the labeled training dataset.
- (5) this procedure is repeated five times. Five iterations are generally sufficient to minimize the error frequency.

Semi-supervised classifiers produced outstanding results in controlled lab experiments

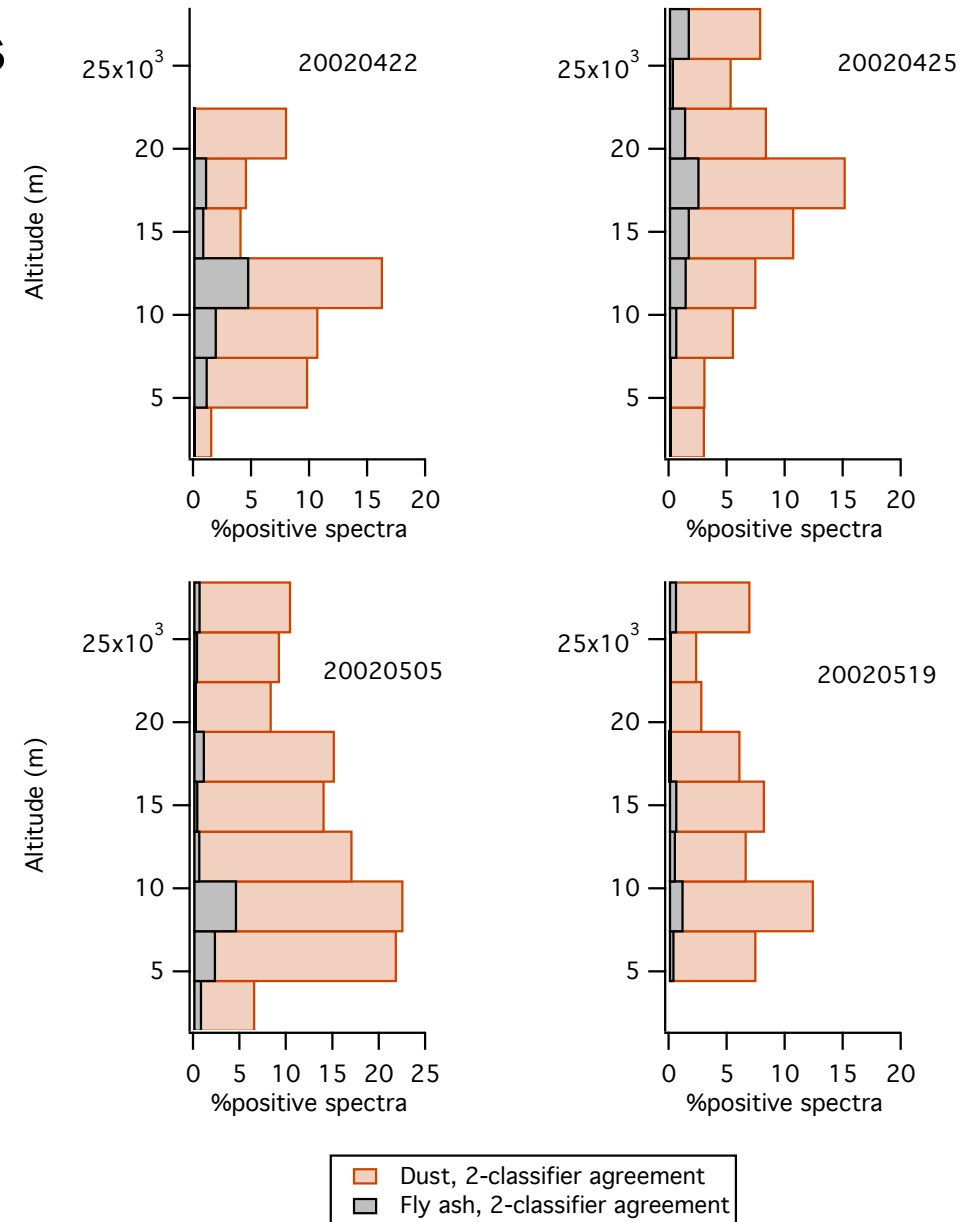

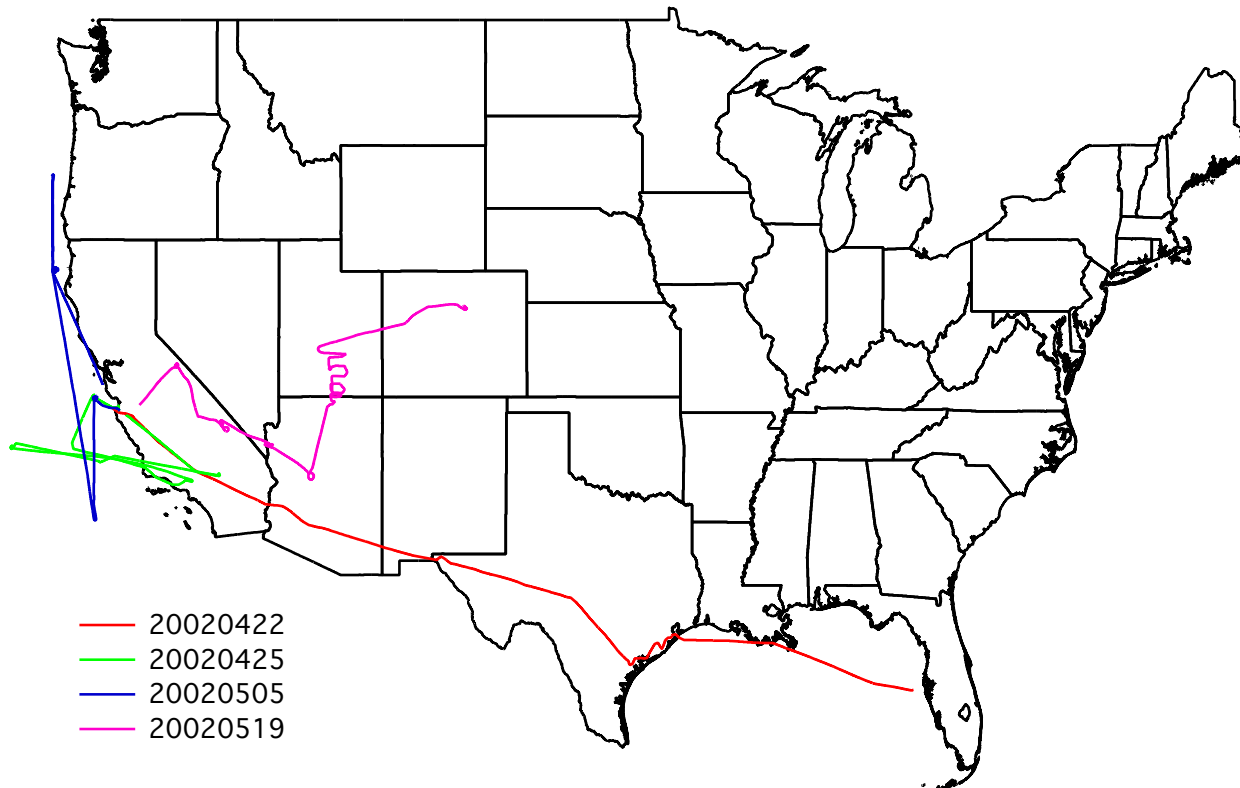

Accuracy: 96.94%

Target Class

...but tend to fall short in real-life situations

Four example flights from ITCT that had the most fly ash hits. Fly ash very strongly correlates with dust. No fly ash-only plumes.

Current approach: using mean-teacher training strategy

- Early results of training stacked autoencoders using mean teacher approach show better accuracy than supervised classification (decision trees, SVM).
- Next step is to increase the training dataset size with more unlabeled examples.
